Abstract

Detecting previously unseen named entities in text is a challenging task. The paper describes how three initial classifier models were built using Conditional Random Fields (CRFs), Support Vector Machines (SVMs) and a Long Short-Term Memory (LSTM) recurrent neural network. The outputs of these three classifiers were then used as features to train another CRF classifier working as an ensemble.

5-fold cross-validation based on training and development data for the emerging and rare named entity recognition shared task showed precision, recall and F1-score of 66.87%, 46.75% and 54.97%, respectively. For surface form evaluation, the CRF ensemble-based system achieved precision, recall and F1-scores of 65.18%, 45.20% and 53.30%. When applied to unseen test data, the model reached 47.92% precision, 31.97% recall and 38.55% F1-score for entity level evaluation, with the corresponding surface form evaluation values of 44.91%, 30.47% and 36.31%.

1 Introduction

The recognition of named entities is inherently complicated by the fact that new names emerge constantly and productively. This is particularly true for social media text and for other texts that are written in a more informal manner, where the issue is further complicated by a higher degree of misspellings as well as different types of unconventional spellings; on social media such as Twitter, abbreviated forms of words are common, as are merging of multiple words, special symbols and characters inserted into the words, etc.

Several approaches to Twitter named entity extraction have been explored, but it is still a challenging task due to noisiness of the texts. Liu et al. (2011) proposed a semi-supervised learning framework to identify Twitter names, using a k-Nearest Neighbors (kNN) approach to label names and taking these labels as an input feature to a Conditional Random Fields (CRF) classifier, achieving almost 80% accuracy on their own annotated data. Ritter et al. (2011) proposed a supervised model based on Labeled LDA (Ramage et al., 2009), and also showed part-of-speech and chunk information to be important components in Twitter named identification. Li et al. (2012) introduced an unsupervised Twitter named entity extraction strategy based on dynamic programming.

The present work addresses emerging and rare entity recognition. The first Twitter named entity shared task was organized at the ACL 2015 workshop on noisy user-generated text (Baldwin et al., 2015), with two subtasks: Twitter named entity identification and classification of those named entities into ten different types. Of the eight systems participating in the first workshop, the best (Yamada et al., 2015) achieved an F1-score of 70.63% for Twitter name identification and 56.41% for classification, by combining supervised machine learning with high quality knowledge obtained from several open knowledge bases such as Wikipedia. Another team, (Akhtar et al., 2015) used a strategy based on differential evolution, getting F1-scores of 56.81% for the identification task and 39.84% for classification.

A second shared task on Twitter Named Entity recognition was organized at COLING in 2016 (Strauss et al., 2016). The best placed system (Limsopatham and Collier, 2016) used a bi-directional LSTM (Long Short-Term Memory) neural network model, and achieved 52.41% and 65.89% F1-scores on entity level and segmentation.
level evaluation, respectively. A system based on Conditional Random Fields (CRFs) and a range of features (Sikdar and Gambäck, 2016) achieved the best recall at segmentation level evaluation, and the second best $F_1$-score (63.22%).

A related shared task on Twitter named entity recognition and linking (NEEL) to the DBpedia database was held in conjunction with the 2016 WWW conference (Cano et al., 2016). Five teams participated, with the best system (Waitelonis and Sack, 2016) achieving recall, precision and F-scores of 49.4%, 45.3% and 47.3%. In that system, each token was mapped to gazetteers developed from DBpedia. Tokens that were not nouns or did not match stop words were discarded.

The present paper outlines an ensemble-based machine learning approach to the identification and classification of rare and emerging named entities. Here the classification categories are Person, Location, Corporation, Product, Creative-work and Group. A Conditional Random Fields (Lafferty et al., 2001) classifier was trained using the outputs from three other classifiers as features, with those classifiers in turn being built using three different learning strategies: CRFs, Support Vector Machines (SVMs), and a deep learning based Long Short-Term Memory (LSTM) recurrent neural network. The rest of the paper is organized as follows: The named entity identification methodology and the different features used are introduced in Section 2. Results are presented and discussed in Section 3, while Section 4 addresses future work and concludes.

2 Name Recognition Methodology

The named entity recognition method is divided into two steps. In the first step, three classifiers are built to recognize named entities using different features from the unstructured text. In the second step, the outputs from the three classifiers are considered as three features and used to train a CRF classifier working as an ensemble learner, to produce the final named entity recognition. The system architecture is shown in Figure 1.

2.1 CRF-based Named Entity Recognition

The Conditional Random Fields Named Entity Recognition model was implemented using the C++ based CRF++ package\(^1\), which allows for fast training by utilizing L-BFGS (Liu and Nocedal, 1989), a limited memory quasi-Newton algorithm for large scale numerical optimization. The CRF classifier was trained with L2 regularization and a range of features:

- local context (-3 to +2)\(^2\),
- part-of-speech information,
- chunk information,
- suffix and prefix characters (-4, +4), and
- word frequency,

Together with a number of Boolean flags, namely, is-word-length $< 5$, is-followed-by-special-character (‘@’ or ‘#’), is-stop-word, is-all-upper-case, is-all-digit, is-alpha-and-digit-together, and is-last-word.

2.2 SVM-based Named Entity Recognition

Since Support Vector Machines previously have been successfully utilized to recognize named entities in formal text, e.g., by Isozaki and Kazawa (2002), a classifier was built using the C++ based SVM package Yamcha\(^3\) with polynomial kernel and default settings. The same features as for the CRF model were used to train the SVMs.

2.3 LSTM-based Named Entity Recognition

The proposed deep learning based named entity recognition model consists of two Long Short-Term Memory recurrent neural network (Hochreiter and Schmidhuber, 1997), a model which was also successfully used by Lample et al. (2016) to achieve state-of-the-art named entity recognition results in formal texts. The first LSTM identifies the boundaries of a named entity (called mention) and this mention is then used as one of the features for named entity recognition in the second LSTM.

For identifying mentions, two binary features, is-start-with-capital-letter and is-all-upper-case, were extracted together with the following:

- word shape-1, a length 6 one-hot vector containing the following six binary flags: upper case, lower case, digit, ’@’ symbol, ‘#’ symbol, and other characters,
- word shape-2, a length 39 one-hot vector consisting of the 26 letters of the English alphabet converted to lower case, together with the ten digits, the two symbols ’@’ and ‘#’, and one spot for other characters, and
- a word2vec pre-trained vector of length 150, Tweets were collected from the W-NUT 2016 shared task,\(^4\) the 2016 NEEL challenge,\(^5\) and the W-NUT 2017 workshop datasets to build the word2vec model (Mikolov et al., 2013a,b). The skip-gram approach was used with negative sampling and a context window of 5. All features were then concatenated into one vector and fed to the first LSTM network for mention recognition.

After a mention had been identified, it was used as one of the features for recognition of named entities in the second LSTM model, which as features together with word-shape-1 and word-shape-2 (as above) utilized three Boolean flags (is-mention, is-start-with-capital-letter, and is-all-upper-case), and GloVe (Pennington et al., 2014), a pre-trained Twitter word vector (here a GloVe vector of dimension 100 was selected).

These features were concatenated to train an LSTM model for 50 epochs with a batch size of 256. The network was set up as consisting of two hidden layers with 256 hidden units.

2.4 A Named Entity Recognition Ensemble

In the second step, the outputs of the above three classifiers were considered as input features to a CRF classifier, which was trained using these three features together with the previous and next two context words. Note that this final CRF classifier being used a selector in the ensemble thus does not cover all features of the CRF classifier described above (Section 2.1), but only utilizes the context and the three classifiers’ outputs as features.

An ensemble based on using majority voting was also tested, which selected the output of one of the classifiers at random, in case they all produced different outputs. The results of the voting-based ensemble improved on the CRF and SVM models, but turned out worse than the LSTM model. However, the ensemble using a Conditional Random Field model to select among the classifier outputs improved results over the board.

3 Experiments

The experiments were based on the datasets provided by the organizers of the W-NUT 2017 shared task on emerging and rare named entity recognition (Derczynski et al., 2017). The statistics of the datasets are shown in Table 1.

3.1 Results

For the experiments, the development data was merged with the training data, and a 5-fold cross-validation was executed. The CRF-based classifier model produced the precision, recall and F\(_1\) values of 51.79%, 45.51% and 48.31%, respectively. The LSTM model performed better when compared to the CRF-based model with respect to recall and F\(_1\)-score, achieving precision, recall and

F\textsubscript{1} values of 51.58%, 51.33% and 51.37%. However, as shown in Table 2, the CRF-ensemble approach outperformed all the other models with respect to F\textsubscript{1}-score. For surface evaluation, a similar behaviour could be observed, with the ensemble model achieving the highest F\textsubscript{1}-score at 53.30%.

The different classifiers were also applied to the unseen test data and produced similar results after 5-fold cross-validation, with the ensemble approach achieving the best F\textsubscript{1}-score compared to all other models, as can be seen in Table 3. The CRF ensemble’s named entity precision, recall and F\textsubscript{1}-score on the test data were 47.92%, 31.97% and 38.55%, respectively. For surface form evaluation, the ensemble system achieved 44.91% precision, 30.47% recall and 36.31% F\textsubscript{1}-score.

Table 4 compares our results (FLYTXT) to the other systems participating in the shared task, with the FLYTXT ensemble-based system placing in 5th position in the final ranking on both named entity and surface form evaluation.

### 3.2 Error Analysis

The system suffers from poor recall, with the model only finding 720 of 1079 named entities in the test data. The system also classified many identified named entities wrongly, and in total correctly identified 345 named entities. This may be due to almost all named entities present in the test data being unknown and fairly dissimilar to the ones appearing in the training data.

### 4 Conclusion

This paper has proposed an ensemble-based system for Twitter named entity identification and classification. A range of different features was developed to extract Twitter names from the tweets. Three initial classifiers were built, one for CRF-based named entity extraction, one utilizing SVMs, and one based on a deep learner (LSTM). The ensemble utilized a CRF classifier taking the output of the other three models as input.

In the future, we will analyse the errors in more detail and aim to use external resources (e.g., DBpedia and Wikipedia) to reduce the misclassification of the tokens, as well as to identify more entities from the tweets. We will also try to generate more models and later ensemble these models to improve the system performance.
